

Supplementary Note for “Unifying single-cell annotations based on the Cell Ontology”

Leveraging the Cell Ontology to classify unseen cell types

The Cell Ontology is a directed acyclic graph (DAG) over cell type labels, which are called Cell Ontology terms in this paper. Edges in this graph represent various semantic relationships. In this paper, we only consider the ‘is a’ relationships, which result in a hierarchy of cell type labels with edges going from general to specific cell type terms. Embedding the Cell Ontology into the low-dimensional space consists of two steps. Firstly, random walk with restart (RWR) is used to calculate a ‘diffusion state’ vector for each cell type according to its distances to all other cell types. This diffusion state vector has a length equals to the total number of cell types in the Cell Ontology graph. Each bit in this vector represents the RWR-based distance to another cell type on the Cell Ontology graph. Secondly, singular value decomposition (SVD) is used to reduce the dimensionality of these high-dimensional features into a low-dimensional space, encoding the embedding vector of each cell type.

Random walk with restart on the Cell Ontology Graph We first perform random walk with restart on the Cell Ontology graph. RWR is different from conventional random walks in that it introduces a pre-defined probability of restarting at the initial cell type after every iteration.

Formally, let \mathbf{A} denote the adjacency matrix of a cell type graph with n cell types, where each node is a cell type and $A_{i,j} = 1$ if and only if cell type i is the child or the parent of cell

type j on the Cell Ontology graph. Let $\mathbf{B}_{i,j}$ be the transition matrix of \mathbf{A} . Each entry $\mathbf{B}_{i,j}$ in the transition matrix \mathbf{B} represents the probability of a transition from cell type i to cell type j and is defined as:

$$\mathbf{B}_{i,j} = \frac{\mathbf{A}_{i,j}}{\sum_{j'} \mathbf{A}_{i,j'}}. \quad (1)$$

Next, let S_i^t be an n -dimensional distribution vector in which each entry stores the probability of a cell type being visited from cell type i after t steps, RWR from cell type i with restart probability p_r is defined as:

$$S_i^{t+1} = (1 - p_r)S_i^t \mathbf{B} + p_r o_i, \quad (2)$$

where o_i is an n -dimensional distribution vector with $o_i(i) = 1$ and $o_i(j) = 0, \forall i \neq j$. Note that the restart probability controls the relative influence of global and local topological information in the diffusion, where a larger value places greater emphasis on the local structure. We can obtain the stationary distribution S_i^∞ of RWR at the fixed point of this iteration, and we refer to this as the ‘diffusion state’ S_i of cell type i (i.e. $S_i = S_i^\infty$), using the same definition as previous work¹. Intuitively, the j th entry S_{ij} stores the probability that RWR starts at cell type i and ends up at cell type j in equilibrium. The fact that two cell types having similar diffusion states implies they are in similar positions with respect to other cell types in the Cell Ontology graph, which may reflect cell type similarity.

However, the diffusion states are not entirely accurate, partially due to the noisy and incomplete nature of the Cell Ontology. Moreover, high dimensionality imposes additional computational constraints on directly using diffusion states as features for classification or regression

tasks.

Dimensionality reduction on cell type diffusion states To address this issue, OnClass employs the following dimensionality reduction scheme as the previous work². The probability assigned to cell type j in the diffusion state of cell type i is modeled as

$$S'_{ij} = \frac{e^{x_i^T z_j}}{\sum_{j'} e^{x_i^T z_{j'}}}, \quad (3)$$

where $\forall i, z_i, x_i \in R^q$ for $q \ll n$. We refer to z_i as the context feature and x_i as the cell type feature of cell type i both capturing the topological properties of the graph. If x_i and z_j are close in direction and have large inner product, then it is likely that cell type j is frequently visited in the random walk starting from cell type i . OnClass takes a set of observed diffusion states $S = \{S_1, \dots, S_n\}$ as input and optimizes over z and x for all cell types, using KL-divergence as the objective function.

Instead of using gradient descent to optimize the loss function, we solve this optimization problem by using the classic singular value decomposition³, which substantially decreases the computation time. To avoid taking a logarithm of zeros, we add a small positive constant to s_{ij} and compute the logarithm diffusion state matrix \mathbf{L} as:

$$\mathbf{L} = \ln(\mathbf{S} + \mathbf{Q}) - \ln(\mathbf{Q}). \quad (4)$$

where $Q \in R^{n \times n}$ with $Q_{ij} = \frac{1}{n}, \forall i, j$. With SVD, we decompose \mathbf{L} into three matrices \mathbf{U} , Σ and \mathbf{V} :

$$\mathbf{L} = \mathbf{U}\Sigma\mathbf{V}^T, \quad (5)$$

where $U \in R^{n \times n}$, $V \in R^{n \times n}$, and $\Sigma \in R^{n \times n}$ is the diagonal singular value matrix. To obtain the low-dimensional vectors z_j and x_i with q dimensions, we simply choose the first q singular vectors U_q , V_q and the first q singular values Σ_d . More precisely, let $\mathbf{X} = \{x_1, \dots, x_n\}$ denote the low-dimensional vector representation matrix, and $\mathbf{Z} = \{z_1, \dots, z_n\}$ denote the context feature matrix. \mathbf{X} and \mathbf{Z} can be computed as:

$$\mathbf{X} = \mathbf{U}_q \Sigma_q^{0.5}, \quad (6)$$

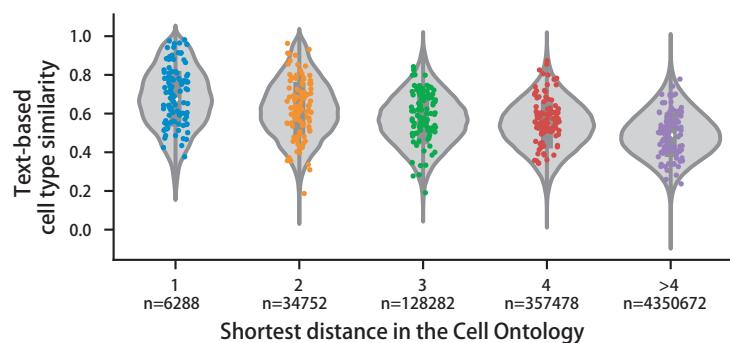

$$\mathbf{Z} = \mathbf{V}_q \Sigma_q^{0.5}, \quad (7)$$

We use $\mathbf{X} = \{x_1, \dots, x_q\}$ to denote the low-dimensional vector representation matrix of cell type labels. x_j is the vector for cell type j . Importantly, our representation captures not only single-hop parent-child relationships, but also more global patterns such as long-range sibling relationships on the Cell Ontology graph.
